

Web Applications with **ASP.NET** Core

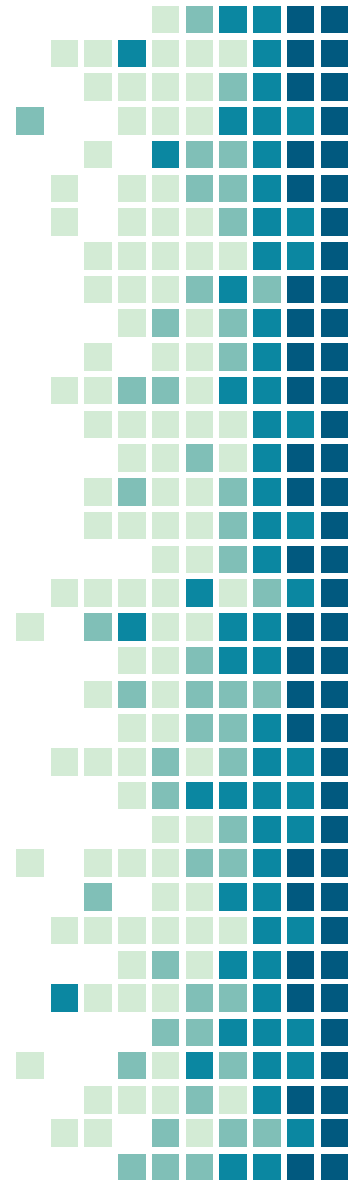

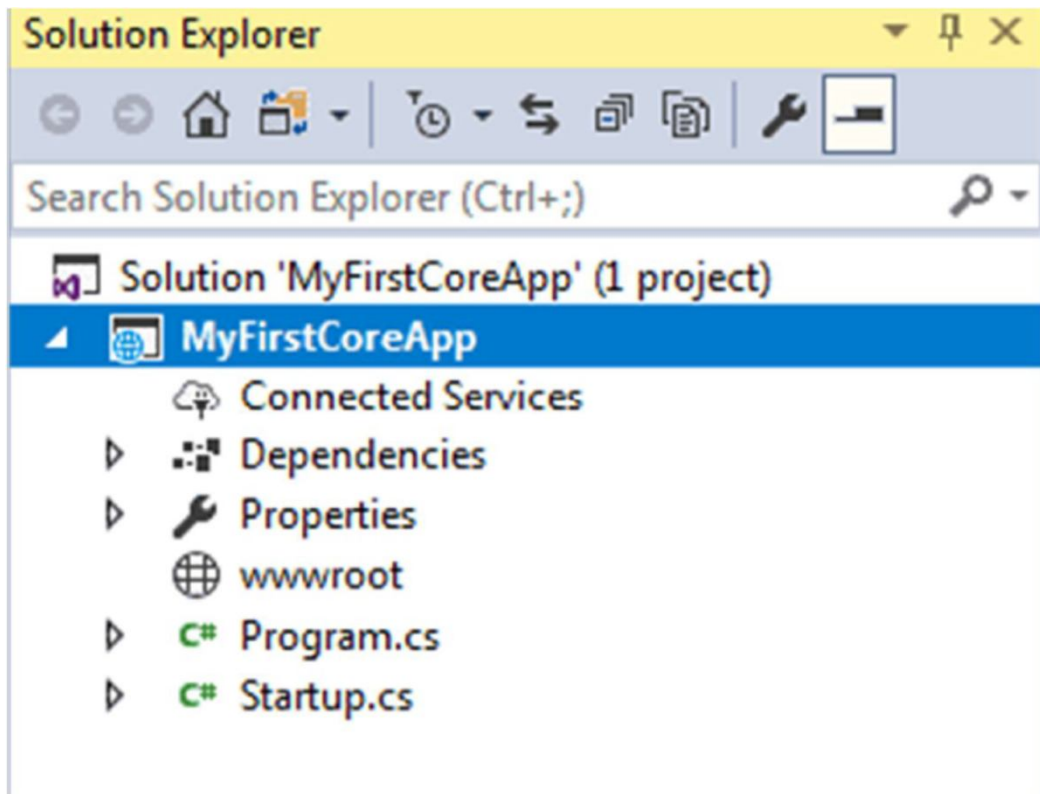

Today's Learning

- Project Structure.
- Comparison ASP.NET Core 5.0 and 6.0 Project.
- Dependencies.
- Properties Sections.
- WWWRoot folder.
- Main Method.
- Startup Class.

Project Structure

Project File

- The csproj file includes settings related to targeted .NET Frameworks, project folders, NuGet package references etc.
- We do not need to unload project for editing the project file. (as old version).
- File References not included in a file. (Files in Root Folder are the part of project)

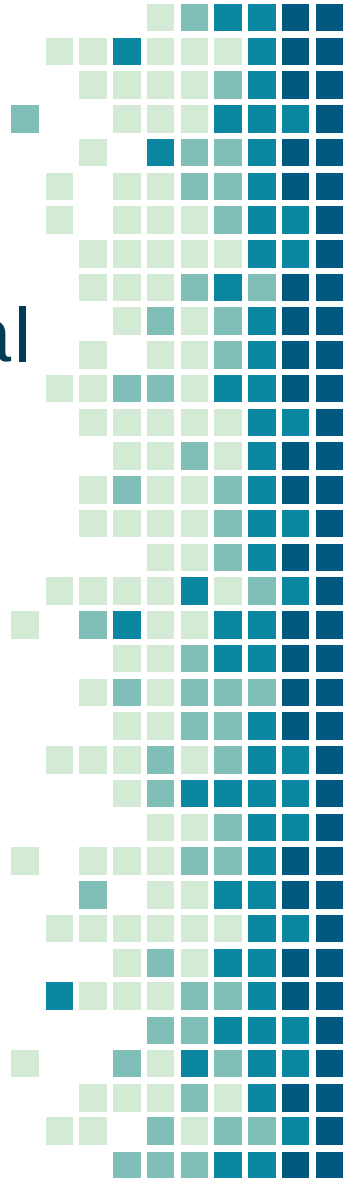

Dependencies

- .csproj file has package reference tag to define the package references. In new asp.net core packages are referenced as dependencies and categories as per the package manager.
- Asp.Net Core also have a concept of meta package it maintains list of packages those can be reference with single entry.
- You can install dependencies using nuget package manager

Properties Section

- The Properties node includes launchSettings.json file which includes Visual Studio profiles of debug settings.
- Launch settings contains the configuration settings for debug profile and development. Which can contain multiple profiles and environment variables and as per the we can write conditional code.

wwwroot folder

- By default, the wwwroot folder in the ASP.NET Core project is treated as a web root folder.
- Static files can be stored in any folder under the web root and accessed with a relative path to that root.
- You can create separate folders for the different types of static files such as JavaScript, CSS,
- Images, library scripts etc.

Main Method

- Initially ASP.NET Core application starts as console application.
- Main method is entry point for application. Where we can configure ,host and run asp.net core application
- CreateWebHostBuilder calls CreateDefaultBuilder method of WebHost it creates default web host with certain preconfigured default settings.

Create Default Builder

- It will Set up the web server.
- Loading the host and application configuration from various configuration sources.
- Configure logging.
- Register Startup class, which contains methods to configure services and Configure Method.

Startup Class.

- In ASP.NET Core, the Startup class provides the entry point for an application, and is required for all applications.
- ASP.NET Core application must include Startup class. It is like Global.asax in the traditional .NET application.
- As the name suggests, it is executed first when the application starts.
- The startup class can be configured using `UseStartup<T>()` method at the time of configuring the host in the `Main()` method of Program class.

Startup Class.

- The name "Startup" is by ASP.NET Core convention.
- However, we can give any name to the Startup class, just specify it as the generic parameter in the UseStartup<T>() method.
- The Startup class must include a Configure method and ConfigureServices method.

Inprocess and Outprocess Hosting

- By default when you run the Application in visual studio It will use the in process hosting model that means it will use the IIS Express Worker Process.
- When we run the application from the command prompt it runs in Out Of Process hosting it Kestrel.
- Kestrel Cross platform web server for asp.net core and it is default server for out process hosting model .
